An Algorithm for Solving 3-Dimensional Assignment Problems with Application to Scheduling a Teaching Practice

A. M. FRIEZE and J. YADEGAR
Department of Computer Science and Statistics, Queen Mary College, University of London

A scheduling problem associated with teaching practices at colleges of education is formulated as a 3-dimensional assignment problem. An efficient algorithm for its solution, based on Lagrangean relaxation, is described.

The problem motivating the work described in this paper is the following: student teachers at colleges of education have periodically to undertake teaching practices. Each of a group of students will be assigned to one of a set of schools and his or her practices will be supervised by a tutor from the college.

Arranging which school each student is assigned to and which tutor will carry out a student's supervision is complicated by the fact that, quite naturally, students and tutors have requirements and preferences, and one should try to arrange things so that these are taken into account.

Formally suppose there are \( m \) students, \( n \) tutors and \( p \) schools. Let \( I = \{1, \ldots, m\}, J = \{1, \ldots, n\}, K = \{1, \ldots, p\} \). For student \( i \in I \), tutor \( j \in J \) and school \( k \in K \) let \( a_{ijk} \) be a satisfaction value associated with an assignment of student \( i \) to school \( k \) under supervision by tutor \( j \).

Tutor \( j \) is willing to supervise no more than \( t_j \) students for \( j \in J \) and school \( k \in K \) can have at most \( s_k \) students assigned to it.

A schedule is a pair \( y, z \) of integer \( m \)-vectors where \( y_i \in J \) and \( z_i \in K \) for \( i \in I \). The triple \((i, y_i, z_i)\) corresponds to student \( i \) being assigned to school \( z_i \) and supervised by tutor \( y_i \).

The schedule is feasible

\[
\|i: y_i = j\| \leq t_j \quad \text{for} \quad j \in J
\]

and

\[
\|i: z_i = k\| \leq s_k \quad \text{for} \quad k \in K.
\]

The value of a schedule is \( \sum_{i \in I} t_{i,y_i,z_i} \). An important objective in arranging a teaching practice is to try and maximise the schedule value.

This problem can be formulated as an integer program in the following way:

Let the 0–1 variable \( x_{ijk} \)

\[
i \in I, j \in J, k \in K
\]

have the following significance:

\[
x_{ijk} = 1 \text{ if student } i \text{ is supervised at school } k \text{ by tutor } j - \text{sometimes referred to as triple } (i, j, k).
\]

\[
= 0 \text{ otherwise.}
\]

We then have the problem AP3:

\[
\text{maximise} \quad \sum_{i \in I} \sum_{j \in J} \sum_{k \in K} t_{ijk} x_{ijk}
\]
subject to
\[ \sum_{j \in J} \sum_{k \in K} x_{ijk} = 1 \quad i \in I \]  
(1b)
\[ \sum_{i \in I} x_{ijk} \leq t_j \quad j \in J \]  
(1c)
\[ \sum_{i \in I} x_{ijk} \leq s_k \quad k \in K \]  
(1d)
\[ x_{ijk} = 0 \text{ or } 1. \quad i \in I, j \in J, k \in K \]  
(1e)

We use the notation \( r(x) \) to denote the sum in (1a).

Constraint set (1b) says each student \( i \) occurs in exactly one triple. Constraint set (1c) says that each tutor \( j \) supervises no more than \( t_j \) students and constraint set (1d) says that each school \( k \) takes no more than \( s_k \) students.

AP3 is a 3-dimensional assignment problem.

It is unfortunately an NP-hard problem—see Garey and Johnson\(^1\) for a detailed analysis of this statement—and as such is unlikely to be solvable by an algorithm with a time bound which is polynomial in the size of the problem.

One is almost forced therefore to use a heuristic as in Frieze\(^2\) or to try a branch and bound approach or possibly a cutting plane approach.

Very little material has been published on this problem. Branch and bound algorithms are described in Pierskalla\(^3\) and Hansen and Kaufman,\(^4\) where only small problems up to size \( m = 8 \) and \( m = 16 \) respectively were solved. (This latter problem took 674 sees on a CDC 6400.)

A branch and bound algorithm using Lagrange multipliers for constraints (1c) and (1d) was tested in Frieze\(^5\) but the results were inferior to those proposed here. Burkard\(^6\) also mentions the possibility of using Lagrangean relaxation on this problem.

We shall describe an approach using the idea of Lagrangean relaxation introduced by Held and Karp\(^7\)—see also Fisher,\(^8\) Geoffrion\(^9\) or Shapiro.\(^10\)

We relax constraints (1d) and use multipliers \( u_k \geq 0 \) for \( k = 1, \ldots, p \) and consider the dual function \( \phi: \mathbb{R}^p \rightarrow \mathbb{R} \) defined by

\[ \phi(u) = \max \sum_{i \in I} \sum_{j \in J} \sum_{k \in K} (r_{ijk} - u_k)x_{ijk} + \sum_{k \in K} s_ku_k \]  
(2)

subject to (1b), (1c), (1e).

If \( x^* \) is an optimum solution for AP3 it is easy to show that

\[ \phi(u) \geq r(x^*) \quad \text{for all } u \in \mathbb{R}^p . \]

The aim is to find a \( u \) that minimises or nearly minimises \( \phi \). This will generally give a good upper bound which can be used in the normal way in a branch and bound algorithm.

The procedure used to ‘minimise’ \( \phi \) is the sub-gradient algorithm. We outline the bounding procedure before going into details.

**PROCEDURE BOUND**

- **Parameters:**
  \( N = \) A limit to the number of iterations to be performed in computing the bound.
  \( \varepsilon \geq 0 = \) A tolerance, i.e. we will be satisfied with a feasible solution \( \hat{x} \) satisfying \( r(\hat{x}) \geq (1 - \varepsilon)r(x^*) \)

- **(Initialisation)**
  \( u = u_0 = \) starting value of \( u \), \( u_0 = 0 \) seems remarkably good
  \( ub = x = \) smallest upper bound computed so far
  \( lb = -\infty = \) value of best solution to AP3 found so far
  \( t = 0 = \) iteration count

- **(Iteration)**
  \( t = t + 1 \)
  If \( t > N \) terminate the algorithm
  Compute \( \phi(u) \), i.e. \( \varphi = \min(ub, \phi(u)) \)
  Use the solution to (2) \( lb = \max(lb, r(\hat{x})) \)
  If \( lb \geq (1 - \varepsilon)ub \) then
    Compute a direction \( d \)
    Compute a step length \( \alpha \)
    \( u_k = \max(0, u_k + \alpha x_k) \)
  Go to (b).

Note that the algorithm will minimises \( \phi \) and bound car

We next provide details of the dual function \( \phi \).

For each \( i \in I, j \in J \) define \( h_{ij} \)

We argue next that

This is proved formally

First let \( (x^*_j) \) be an optimal solution

\( (\xi_t) \) satisfies (4b) and (4c)

Also

Suppose next that \( (\xi_t) \) satisfies (4b) and (4c)

Continuing the sequence
(b) \( t = t \cdot 1 \) if \( t > X \) terminate bound
(c) Compute \( \phi(u) \), i.e. solve (2)
\( \bar{u} = \min(u, \phi(u)) \)
(d) Use the solution to (2) to generate a solution \( \hat{x} \).
\( \bar{h} = \max \left( l_{ij}, t(\hat{x}) \right) \)
If \( \bar{h} \geq 1 - \varepsilon \) terminate bound.
(e) Compute a direction of search \( \mu \).
(f) Compute a step length \( \sigma > 0 \).
(g) \( u_k = \max(0, u_k + \sigma \mu_k) \quad k \in K \)

Go to (b).

Note that the algorithm will have the property that if \( \mu = 0 \) in step (e), then the current \( u \) minimises \( \phi \) and bound can be terminated.

We next provide details for the various undefined steps.

**COMPUTING \( \phi \)**

For each \( i \in I, j \in J \) define \( h_{ij} \in K \) and \( w_{ij} \) by

\[ w_{ij} = t_{ij} - u_{h_{ij}} = \max_{k \in K} (t_{ij} - u_k). \tag{3} \]

We argue next that

\[ \phi(u) = \max \sum_{i \in I} \sum_{j \in J} w_{ij} \tilde{z}_{ij} + \sum_{k \in K} s_k u_k \tag{4a} \]

subject to

\[ \sum_{j \in J} \tilde{z}_{ij} = 1 \quad i \in I \tag{4b} \]

\[ \sum_{i \in I} \tilde{z}_{ij} \leq t_j \quad j \in J \tag{4c} \]

\[ \tilde{z}_{ij} = 0 \text{ or } 1 \tag{4d} \]

This is proved formally as follows:

First let \( (x_{ij}^*) \) be an optimum solution to (2). Let \( \tilde{z}_{ij}^* = \sum_{k \in K} x_{ij}^* \). (1b) and (1c) imply that \( (\tilde{z}_{ij}^*) \) satisfies (4b) and (4c). The integrality of \( (\tilde{z}_{ij}^*) \) plus (4b) implies (4d).

Also

\[ \sum_{i \in I} \sum_{j \in J} \sum_{k \in K} (t_{ij} - u_k)x_{ij}^* \tag{5a} \]

\[ \leq \sum_{i \in I} \sum_{j \in J} \sum_{k \in K} (t_{ij} - u_{h_{ij}})x_{ij}^* \tag{5b} \]

\[ = \sum_{i \in I} \sum_{j \in J} w_{ij} \tilde{z}_{ij} \tag{5c} \]

Suppose next that \( (\hat{z}_{ij}) \) is an optimum solution to (4). Define \( (\hat{x}_{ij}) \) by

\[ \hat{x}_{ij} = \tilde{z}_{ij} \]

\[ \hat{x}_{ij} = 0 \text{ otherwise.} \]

Continuing the sequence of equations and inequalities (5) we get

\[ \leq \sum_{i \in I} \sum_{j \in J} w_{ij} \hat{z}_{ij} \tag{5d} \]

\[ = \sum_{i \in I} \sum_{j \in J} \sum_{k \in K} (t_{ij} - u_k)\hat{x}_{ij}. \tag{5e} \]
Now \((\hat{x}_{ijk})\) can be seen to satisfy (1b), (1c) and (1e). As \((x^*_{ijk})\) is optimal, this implies that the inequalities in (5) can be replaced by equations, which gives our result.

Problem (4) is relatively easy to solve. We used a primal-dual algorithm based on that of Ford and Fulkerson\(^{11}\). We had a program available for this algorithm and so we used it.

**FINDING GOOD SOLUTIONS TO AP3**

The vector \((x_{ijk}^*)\) obtained from solving (2) does not necessarily satisfy (1d) but it does satisfy the remaining constraints of AP3.

The following decomposition of solutions to AP3 was noted in Frieze\(^{2}\) any 0–1 vector \((x_{ijk})\) satisfying (1b) can be decomposed into \(x_{ijk} = \xi_{ij} \eta_{ik}\) where \(\xi, \eta\) satisfy (4b) and

\[
\sum_{k \in K} \eta_{ik} = 1, \quad \text{for } i \in I \tag{6a}
\]

(1c) is then satisfied if and only if (4c) is, and (1d) is satisfied if and only if

\[
\sum_{i \in I} \eta_{ik} \leq s_k, \quad \text{for } k \in K \tag{6b}
\]

In other words AP3 can be shown equivalent to the problem

\[
\text{maximise } \sum_{i \in I} \sum_{j \in J} \sum_{k \in K} t_{ijk} \xi_{ij} \eta_{ik} \tag{7a}
\]

subject to (4b), (4c), (6a), (6b):

\[
\xi_{ij}, \eta_{ik} = 0 \text{ or } 1, \quad i \in I, j \in J, k \in K \tag{7b}
\]

(One can in fact drop the integrality requirement for \(\xi, \eta\) but it does not help very much.)

Having solved (4), we have (hopefully) a good value for \(\hat{x}\). Let this be \(\hat{x}^*\). We can construct the \(\eta\) that maximises (7) given \(\hat{x} = \hat{x}^*\) as follows:

Let \(a_{ik} = \sum_{j \in J} t_{ijk} \hat{x}_{ijk}^*\) for \(i \in I, k \in K\).

The \(\eta\) that maximises (7) under the constraint \(\hat{x} = \hat{x}^*\) is one that maximises

\[
\sum_{i \in I} \sum_{k \in K} a_{ik} \eta_{ik} \tag{8}
\]

subject to (6a), (6b), (7b).

Thus solving 2 problems of the form given in (4) giving an upper bound and a good solution to AP3. Our experiments show that these are of high quality.

**CHANGING \(u\)—THE SUBGRADIENT ALGORITHM**

The function \(\phi\) can be shown to be convex. A vector \(v \in \mathbb{R}^p\) is said to be a sub-gradient of \(\phi\) at \(u\)—written \(v \in \partial\phi(u)\) if

\[
\phi(u') - \phi(u) \geq v \cdot (u' - u) \quad \text{for all } u' \in \mathbb{R}^p \tag{9}
\]

The sub-gradient generalises the idea of a gradient. (Note that \(\phi\) is not generally differentiable everywhere.) The sub-gradient algorithm generalises the classical steepest descent algorithm—see Held, Wolfe and Crowder,\(^{12}\) Poljak\(^{13}\) or Camerini, Fratta and Maffioli.\(^{14}\)

So in step (e) of our algorithm the direction taken \(\mu\) is such that \(-\mu \in \partial\phi(u).\) (Note that in (9) if \(\phi(u) < \phi(u)\) and \(-u \in \partial\phi(u),\) then

\[
0 > \phi(u) - \phi(u) - \mu \cdot (u - u) \rightarrow \mu \cdot (u - u) > 0,
\]

and so \(u' - u\) makes an acute angle with the direction \(\mu\) chosen.)
COMPUTING $\mu$

Finding a sub-gradient is fortunately a 'by-product' of the calculation of $\phi$. In fact if $(x^*, \eta)$ solves (2), then it is not difficult to show that $v = (v_1, \ldots, v_p)$ where

$$v_k = s_k - \sum_{i \in I} \sum_{j \in J} x^*_{ijk} \quad k \in K$$

(10)

is a sub-gradient of $\phi$ at $u$.

Having obtained a sub-gradient, one needs to decide on the step length $\sigma$. The following result is useful: suppose $u^*$ minimises $\phi$ and $v \in \partial \phi(u)$, then for $0 < \lambda < 2$ we have

$$\|u^* - (u - \sigma v)\| < \|u^* - u\|$$

Euclidean norm

(11a)

if

$$\sigma < \frac{\lambda \phi(u) - \phi(u^*)}{\|v\|^2}.$$ (11b)

As $\phi(u^*)$ is not known, we underestimate it by using $lb$. This works satisfactorily in practice. We used $\lambda = 1$ in our experiments.

If the procedure (a)-(g) described above fails to find a satisfactory solution after $N$ steps, one branches, i.e. split the problem into a number of subproblems and apply the bounding procedure to each subproblem and so on.

Our code does not have this facility. We believe that we will usually get good enough solutions for teaching practice problems without branching.

Some experimental results and implementational details are discussed next.

COMPUTATIONAL CONSIDERATIONS

We have up to the present time only tackled one problem arising from a teaching practice. The rest of our experience is on randomly generated problems.

In a teaching practice problem the values $t_{ijk}$ are generated in the following way: the input data consists of 3 matrices $A, B, C$. $A = [a_{ij}]$ is $m \times n$, $B = [b_{jk}]$ is $m \times p$ and $C = [c_{jk}]$ is $n \times p$. The matrix $a_{ij}$ has the following significance:

$$a_{ij} = 0 \quad \text{if student } i \text{ cannot be supervised by tutor } j.$$ (7a)

$$> 0 \quad \text{the 'satisfaction level' is } a_{ij}. \text{ In practice we allow } a_{ij} = 1 \text{ or } 2.$$ (7b)

The values $b_{jk}$ for student-school and $c_{jk}$ for tutor-school are defined similarly. The values for $t_{ijk}$ can then be defined as

$$t_{ijk} = a_{ij} + b_{jk} + c_{kj} \quad \text{if } a_{ij}, b_{jk}, c_{kj} = 0.$$ (12)

$$= -\infty \quad \text{otherwise}$$

i.e. the primary task is to find as large as possible a set of triples $(i, j, k)$ such that $a_{ij} = 0$, $b_{jk} = 0$ and $c_{kj} = 0$. The value for $\tau$ in (12) was taken as $M = 6m + 1$. In practice we did not use (12) but

$$t_{ijk} = M + (t_{ijk} \text{ as defined in (12)}).$$ (13)

Using (13) we have that at any stage $[uh/m]$ is a valid upper bound to the number of students that can be found suitable assignments.

We found it useful having input the matrices $A, B, C$ to generate a list of $L$ of triples $(i, j, k)$ for which $t_{ijk} = -\infty$ in (12). In the practical problem we tackled where $m = 57$, $n = 29$ and $p = 106$ only 2430 out of the 175218 possible triples were included in $L$. This speeded up the construction of the matrix $W = [w_{ij}]$ in (3) enormously. In fact construction of $W$ at each stage was a bottleneck that had to be overcome if the method was to be practicable. Construction directly from (3) was initially taking up approximately 80% of the time for each iteration.

Now one pass through $L$ is all that is needed to update $W$.

It may also be worth mentioning that we do not need to keep room for 0-1 vectors $(x_{ijk}), (x_{ij}), (x_{ik})$. We work throughout with corresponding integer $m$-vectors $y, z.$
RESULTS

In Tables 1 and 2 we summarise our computational experience with the method described previously. All problems were randomly generated except for the last problem in Table 1.

m, n, p are as previously described.

nz = number of non-zero rijk; ub = final upper bound computed; lb = value of best solution found; nit = number of iterations of subgradient algorithm; t = c.p.u. time in seconds on an ICL 1905 computer; (quantities) refers to a version of the program that does not keep the non-zero rijk's in a list — where significantly different.

The problems in Table 1 have the following form: given 3 0-1 matrices A, B, C we take

\[ v_{ijk} = a_{ij} \times h_{ik} \times c_{kj} \text{ for } i \in I, j \in J, k \in K. \]

The most impressive result is that for the practical problem 8, where after one iteration the algorithm assigned the maximum possible number of students.

The quality of this result explains why we have not programmed a branch and bound phase. This would be justified however for problems 6 and 7.

In the problems of Table 2 we took the value \( v_{ijk} = a_{ij} + h_{ik} + c_{kj} \) where \( a_{ij}, h_{ik}, c_{kj} \) were randomly generated integers from a uniform distribution on the interval [0-10].
